Energy-Source-Aware Cost Optimization for Green Cellular Networks with Strong Stability

Weixian Liao, Student member, IEEE, Ming Li, Member, IEEE, Sergio Salinas, Student member, IEEE, Pan Li, Member, IEEE, and Miao Pan, Member, IEEE

Abstract—Last decade witnessed the explosive growth in mobile devices and their traffic demand, and thereby the significant increase in the energy cost of the cellular service providers. One major component of the service providers’ operational expenditure comes from the operation of cellular base stations using grid power or diesel generators when grid power is absent, which also cause adverse environmental impact due to enormous carbon footprint. Therefore, from the service providers’ perspective, how to effectively reduce the energy cost of base stations while satisfying cellular users’ soaring traffic demands has become an imperative and challenging problem. In this paper, we investigate the minimization of the long-term time-averaged expected energy cost of cellular service providers while guaranteeing the strong stability of the network. Specifically, we first formulate the problem by jointly considering flow routing, link scheduling, and energy (i.e., renewable energy resource, energy storage unit, etc.) constraints. Since the formulated problem is a time-coupling stochastic Mixed-Integer Non-Linear Programming (MINLP) problem, which is prohibitively expensive to solve, we reformulate the problem by employing Lyapunov optimization theory. A decomposition based algorithm is developed to solve the problem and the network strong stability is proven. We then derive and prove both the lower and upper bounds on the optimal result of the original problem. Simulation results demonstrate the tightness of the obtained bounds and the efficacy of the proposed scheme.

Keywords—Green cellular network, Lyapunov optimization, network strong stability.

1 INTRODUCTION

As the mobile devices, such as smart phones, tablets, are spreading around the world, various applications such as web browsing, video streaming, and online social networks are shifted from computers to mobile devices, leading to a rocketing increase of data traffic in cellular networks. In order to meet the subscribers’ tremendous traffic demand, cellular service providers have to significantly increase the numbers of their base stations (BSs), and bear the burden of much higher energy costs. In particular, the number of cellular BSs all over the world has increased from a few hundred thousands to more than 4 million, and each of them consumes an average of 25 MWh per year [2]. Studies show that the radio network itself adds up to 80% of an operator’s entire energy consumption, which represents a significant portion of a network operator’s overall expenditures [3]. Therefore, it is of great urgency to find effective solutions to reduce energy costs and develop “green” cellular networks while satisfying mobile users’ ever-increasing traffic demand.

In order to reduce the escalating energy cost in cellular networks, renewable energy, e.g., biofuels, solar and wind energy, has emerged as a feasible alternative to the traditional energy sources. For example, an off-grid base station consumes more than 1500 liters of diesel per month [2]. Using renewable resources to power such cell sites would be much less expensive and more environmentally friendly. It is expected that more than 8% of base stations will be powered by renewable energy by 2014 [4]. Particularly, Ericsson [5] and Nokia [6] have developed green BSs that are running on solar power and wind power, respectively, without using any grid power. Mobile manufacturers like Samsung and Nokia have released a series of future phones which contain solar panels [7].

In this paper, we investigate how to minimize the energy cost of cellular networks while still satisfying users’ traffic demand by considering energy-efficient wireless architectures, renewable energy integration, and network stability. Specifically, we consider a multi-hop cellular network consisting of a number of cellular users, a group of base stations, and a set of available spectrum bands. We envision that each node is equipped with a renewable energy resource, for example, a solar panel (e.g., for each mobile user) or a wind turbine (e.g., for each base station), as well as an energy storage unit [5]–[7]. Both spectrum bandwidths and renewable energy resource outputs are modeled as random processes. In this network, mobile users may communicate with each other or with base stations via multiple hops, rather than a single hop as in traditional cellular networks. Thus, communications can take advantage of locally available spectrums and link rate adaptivity, and hence provide much higher network capacity.

We first formulate an offline energy cost minimization problem, by jointly exploring renewable energy resource allocation, routing, and link scheduling, which turns out to be a time-coupling stochastic Mixed-Integer Non-Linear Programming (MINLP) problem. Previous approaches usually solve such problems based on Dynamic Programming and suffer from the “curse of dimensionality” problem [8]. Full statistical information of the random variables is required to solve the problem, which may be difficult to obtain in practice. Therefore, we
reformulate the problem by employing Lyapunov optimization theory [9] and propose an online energy-source-aware cost minimization problem.

Considering that the formulated online energy-source-aware cost minimization problem is an MINLP problem, which is in general NP-hard [10] and needs to be solved in each time slot, we decompose it and propose an approximation algorithm to solve it efficiently. Specifically, by introducing virtual queues, we are able to decompose the reformulated problem into four subproblems: link scheduling, resource allocation, routing, and energy management. We develop three algorithms to solve the first three subproblems, respectively, based on current network states only. After the first three subproblems are solved, the fourth subproblem can be easily solved as well. We prove that the proposed decomposed based algorithm guarantees that all queues in the network are finite, i.e., network strong stability, which has rarely been achieved before. Moreover, while the approximation algorithm leads to an upper bound on the optimal result of the original problem, a lower bound is also found by solving a relaxed online Linear Programming (LP) problem.

The main contributions of this paper are briefly summarized as follows:

- We formulate an offline energy cost minimization problem by considering dynamic spectrum and renewable energy resource availability, routing, link scheduling, and energy resource allocation.
- We formulate an online energy-source-aware cost minimization problem and propose a decomposition based algorithm to solve the problem efficiently while guaranteeing the strong stability of all queues in the network, i.e., network strong stability.
- We obtain and prove the lower and upper bounds on the optimal result of the original offline energy cost minimization problem.
- Simulation results demonstrate that the obtained lower and upper bounds are very tight, and that the proposed scheme results in noticeable energy cost savings.

The rest of this paper is organized as follows. We discuss related work in Section 2. Section 3 briefly introduces our system models. The energy cost problem is formulated in Section 4 while considering network dynamics and energy management. In Section 5, we reformulate an online energy-source-aware cost minimization problem, which is solved by the proposed decomposition based algorithm. Proofs for the network strong stability and derivation of both the lower and upper bounds on the optimal result of the offline optimization problem are given in Section 6. Extensive simulations are conducted in Section 7, followed by the conclusion drawn in Section 8.

2 RELATED WORK

The rising energy costs and carbon footprint of cellular networks have led to many efforts to address the energy efficiency issues and develop the “green cellular networks” [11], [12]. Chen et al. in [13] have shown the breakdown of power consumption in a typical cellular network and identified several key research components of energy efficiency with network performance, which include deployment efficiency, throughput guarantee, stability of the network, etc. In particular, the energy consumption of a BS can be reduced by improving the BS hardware design, for example, the efficiency of power amplifiers (PAs) [14]. A PA dominates the energy consumption of a BS and its energy efficiency depends on the frequency band, modulation and operating environment [15]. We can also reduce BSs’ energy consumption by including additional software and system features to balance between energy consumption and network performance, e.g., shutting down BSs during low traffic hours, cell zooming or green base station [16]–[21]. Chiaraviglio et al. [16] first investigated the possibility of energy savings of BS switching-on/off by simulation. Niu et al. [17] proposed centralized and distributed algorithms for cell zooming to avoid coverage hole when BSs are turned off. Their another work in [18] studied the smaller and denser cell deployment when cell zooming is not sufficient. Oh et al. [19] proposed a distributed algorithm for BS switching off by considering network-impact, which is an effect caused by turning off a BS. Han et al. [21] also took advantage of green BSs by maximizing the green energy usage. However, such system level approaches degrade the cellular network performance and some cellular users can get disconnected.

Beyond the advance of BS development and control itself, it is crucial to consider various paradigm-shifting technologies like multi-hop relaying in order to enhance the energy efficiency of cellular networks. Particularly, multi-hop relaying has been introduced into cellular networks to improve network throughput [22]–[27]. In fact, since multi-hop communications divide direct paths between mobile terminals and BSs into shorter links [28], in which wireless channel impairments such as path loss are less destructive, lower transmission power can be assigned to the BSs and relays and hence network energy consumption can also be saved. It has been shown in [29] that using multi-hopping in CDMA cellular networks can reduce the average energy consumed per call. In this study, the multi-hop relaying becomes much more challenging since it is coupled with link scheduling and energy management.

Besides, although energy consumption optimization has been studied in wireless networks before [30]–[34], renewable energy has not been considered. In addition, stability is another important concern in cellular networks, while unstable networks result in big packet loss and the failure of service delivery. In the literature, Lyapunov optimization techniques have been adopted to investigate such problems in wireless networks [35]–[41]. Unfortunately, [35]–[37] cannot guarantee that all queues are finite. [38]–[40] develop opportunistic scheduling schemes, which maintain finite queue sizes by dropping some packets. [9], [41] propose joint stability and utility optimization algorithms, but assume that the users’ input data rate is interior to the network capacity region. Thus, in spite of these existing studies, none of the developed algorithms can be adopted to keep all queues finite in our system.
3 SYSTEM MODELS

3.1 Network Model

As shown in Fig. 1, we consider a multi-hop cellular network that consists of \( U = \{1, 2, \ldots, u, \ldots, U\} \) users and \( B = \{1, 2, \ldots, b, \ldots, B\} \) base stations. Let \( N = U \cup B \). We denote the set of available spectrum bands by \( M = \{1, 2, \ldots, m, \ldots, M\} \), and assume that the bandwidth of band \( m \) is a random process denoted by \( \{W^m(t)\}_{t=0}^\infty \), which can be observed at the beginning of each time slot.

In addition, due to their different geographical locations, different nodes may have different available spectrum bands. Denote by \( M_i \subseteq M \) the set of available spectrum bands that node \( i \in N \) can access. Thus, it is possible that \( M_i \neq M_j \) for \( i \neq j, i, j \in N \). Assume the system operates in a time-slotted manner. Suppose there is a set of downlink Internet service sessions denoted by \( S = \{1, 2, \ldots, s, \ldots, S\} \), each of which is denoted as a tuple \( \{d_{s}, v_{s}(t), s_{s}(t)\} \) where \( d_{s} \) stands for the destination of service session \( s \), \( v_{s}(t) \) is the required throughput (in terms of the number of packets) in time slot \( t \), and \( s_{s}(t) \) stands for the source base station of service session \( s \) in time slot \( t \).

3.2 Link Capacity

A widely used model [42], [43] employed for power propagation gain between node \( i \) and \( j \), denoted by \( g_{ij} \), is 

\[ g_{ij} = C \cdot |d(i,j)|^{-\gamma} \]

where \( d(i,j) \) is the Euclidean distance between \( i \) and \( j \), \( \gamma \) refers to the path loss exponent, and \( C \) is a constant related to the antenna profiles of the transmitter and the receiver, wavelength, etc.

We adopt the Physical Model [42], [44] as the interference model, i.e., a data transmission is successful only if the received signal-to-interference plus noise ratio (SINR) is no less than a threshold \( \Gamma \). Specifically, if node \( i \) sends data to node \( j \) on band \( m \) in time slot \( t \), the capacity can be calculated as

\[
c_{ij}^m(t) = \begin{cases} W^m(t) \log_2(1 + \Gamma), & \text{if } SINR_{ij}^m(t) \geq \Gamma \\ 0, & \text{otherwise.} \end{cases}
\]

where \( SINR_{ij}^m(t) \), the SINR of the signal sent from \( i \) to \( j \) on band \( m \) in time slot \( t \), is

\[
SINR_{ij}^m(t) = \frac{g_{ij}P_{ij}^m(t)}{\eta_jW^m(t) + \sum_{j \in N, j \neq i} g_{kj}P_{kj}^m(t)}
\]

Here, \( \eta_j \) is the thermal noise power density at the receiver \( j \), \( P_{ij}^m(t) \) is the transmission power of node \( i \) to node \( j \) on band \( m \) in time slot \( t \), and \( P_{kj}^m(t) \) is the transmission power of an interfering node \( k \) to its receiver \( v \) on band \( m \) in time slot \( t \).

We also denote the maximum transmission power of node \( i \) by \( P_{i}^{\text{max}} \).

3.3 Energy Consumption

For a node \( i \) (\( i \in N \)), its consumed energy in time slot \( t \), denoted by \( E_i(t) \), is attributed to the energy needed to feed the antenna denoted by \( E_i^{\text{const}} \), the energy consumed when staying in idle mode denoted by \( E_i^{\text{idle}} \), and the energy for serving the traffic \( E_i^{TX}(t) \), i.e. [45],

\[
E_i(t) = E_i^{\text{const}} + E_i^{\text{idle}} + E_i^{TX}(t).
\]

\( E_i^{TX}(t) \) will be introduced later.

3.4 Renewable Energy Generation and Energy Storage

We assume that each node \( i \) in \( N \) has a renewable energy resource, for example, a solar panel (e.g., for each mobile user) or a wind turbine (e.g., for each base station). The output of node \( i \)'s renewable resource, denoted by \( R_i(t) \), is an i.i.d. stochastic process that satisfies \( 0 \leq R_i(t) \leq R_i^{\text{max}} \), where \( R_i^{\text{max}} \) is the maximum energy output and a constant. This is because the output of a renewable energy resource mainly depends on meteorological conditions and is dynamic.

We also assume that every node \( i \) has its own energy storage unit, e.g., a battery, for storing energy obtained from its renewable energy resource or drawn from the power grid, which can be used at later time slots. Thus, node \( i \)'s renewable resource output \( R_i(t) \) can be used to charge the energy storage device or serve \( i \)'s energy demand, i.e.,

\[
R_i(t) = c_i^r(t) + r_i(t),
\]

where \( c_i^r(t) \) and \( r_i(t) \) are the energy used for charging node \( i \)'s energy storage unit and serving node \( i \)'s current energy demand, respectively.

In addition, notice that node \( i \)'s energy storage unit works as an energy buffer, whose energy level, denoted by \( c_i(t) \), can be modeled as an energy queue, i.e.,

\[
x_i(t + 1) = x_i(t) + c_i(t) - d_i(t).
\]

where \( d_i(t) \) is the energy discharged from the energy storage unit for serving node \( i \)'s energy demand, and \( c_i(t) \) is the energy charging the energy storage unit, i.e.,

\[
c_i(t) = c_i^r(t) + \omega_i(t)c_i^2(t)
\]

\[
\omega_i(t) = \begin{cases} 1, & \text{if } i \in B \\ \xi_i(t), & \text{if } i \in U \end{cases}
\]

where \( c_i^r(t) \) is the energy drawn from the power grid and \( \omega_i(t) \) indicates whether node \( i \) is connected into the power grid in time slot \( t \). Note that base stations are always connected to the grid while mobile terminals are only occasionally connected. Thus, we assume that \( \{\xi_i(t)\}_{t=0}^\infty \) is an i.i.d. random process where \( \xi_i(t) \in \{0, 1\} \).

Due to the fact that serving node \( i \)'s energy demand \( E_i(t) \) by directly using energy from the grid or from the renewable energy resource, is more efficient than by first charging the
energy storage unit and then discharging it, we have the following two constraints

\[ 1_{d_i(t)>0} + 1_{c_i(t)>0} \leq 1 \]  
(7)

\[ 1_{d_i(t)>0} + 1_{c_i(t)>0} \leq 1 \]  
(8)

where \( 1_A \) is an indicator function that is equal to 1 when the event \( A \) is true, and zero otherwise. Notice that the above constraints (7) and (8) will hold whenever the following inequality holds:

\[ 1_{c_i(t)>0} + 1_{d_i(t)>0} \leq 1 \]  
(9)

Besides, denote by \( x_i^{\text{max}} \) the maximum amount of energy that can be stored by node \( i \)'s energy storage unit. Then, we need

\[ 0 \leq x_i(t) \leq x_i^{\text{max}}. \]  
(10)

Denote by \( c_i^{\text{max}} \) and \( d_i^{\text{max}} \) the maximum amount of energy that node \( i \)'s energy storage unit can be charged with and that can be discharged from node \( i \)'s energy storage unit during a single time slot, respectively. Thus, we have

\[ c_i(t) \leq \min\{c_i^{\text{max}}, x_i^{\text{max}} - x_i(t)\} \]  
(11)

\[ d_i(t) \leq \min\{d_i^{\text{max}}, x_i(t)\}. \]  
(12)

From (11) and (12), we get \( c_i(t) + d_i(t) \leq x_i^{\text{max}} - x_i(t) + x_i(t) = x_i^{\text{max}}, \) which should hold for any \( c_i(t) \) and \( d_i(t) \) that satisfy (11) and (12). Since \( c_i(t) \leq c_i^{\text{max}} \) and \( d_i(t) \leq d_i^{\text{max}} \), we also have the following constraint:

\[ c_i^{\text{max}} + d_i^{\text{max}} \leq x_i^{\text{max}}. \]  
(13)

### 3.6 Definitions

Next, we introduce some definitions and theorems that would be used later in this paper [9].

**Definition 1:** The time average of a random process \( a(t) \), denoted by \( \bar{a} \), is \( \bar{a} = \lim_{T \to \infty} \frac{1}{T} \sum_{t=1}^{T-1} a(t) \).

**Definition 2:** A discrete time process \( a(t) \) is rate stable if \( \lim_{t \to \infty} a(t) = 0 \) with probability 1, and strongly stable if \( \lim_{T \to \infty} \sup_{T} \sum_{t=0}^{T-1} \mathbb{E}[a(t)] < \infty \).

**Theorem 1:** Queue Rate Stability

Let \( Q(t) \) denote the queue length of a single-server discrete time queueing system, whose initial state \( Q(0) \) is a non-negative real-valued random variable, and future states are driven by stochastic arrival and server processes \( a(t) \) and \( b(t) \) according to the following dynamic equation:

\[ Q(t+1) = \max\{Q(t) - b(t), 0\} + a(t) \]  
for \( t \in \{0, 1, 2, \ldots\} \).

Then \( Q(t) \) is rate stable if and only if \( \bar{a} \leq \bar{b} \).

**Theorem 2:** Necessity for Queue Strong Stability

If a queue \( Q(t) \) is strongly stable, and there is a finite constant \( c \) such that either \( a(t) + b(t) \leq c \) with probability 1 for all \( t \) (where \( b(t) \) is \( \bar{b} \) - \( \min\{b(t), 0\} \)), or \( b(t) - a(t) \leq c \) with probability 1 for all \( t \), then \( Q(t) \) is rate stable, i.e., \( \bar{a} \leq \bar{b} \).

Besides, we say that a network is rate stable or strongly stable if all queues in this network are rate stable or strongly stable as described above.

### 4 Dynamic Energy Cost Optimization

In this section, we investigate the dynamic energy cost minimization problem in a multi-hop cellular network.

#### 4.1 Network Layer Design

Recall that we consider downlink traffic in the network. Specifically, the destination nodes are served by the base stations via multiple hops, with the help of other nodes. Therefore, as the network layer buffer, each node \( i \) maintains a data queue \( Q^s_{i,t} \) for each service session \( s \). The queueing law for \( Q^s_{i,t} \) is as follows:

\[ Q^s_{i,t} + 1(t+1) = \max\{Q^s_{i,t}(t) - \sum_{j \in N^s, j \neq i} l^s_{ij}(t), 0\} \]

\[ + \sum_{j \in N^s, j \neq i} l^s_{ji}(t) + k_s(t) \cdot 1_{i = s_{i}(t)}, \]  
(15)

where \( l^s_{ij}(t) \) is the number of packets transmitted from \( i \) to \( j \) for service session \( s \) in time slot \( t \), and \( k_s(t) \) (\( 0 \leq k_s(t) \leq K^{s\text{max}}_s \)) is the number of packets that the source base station of service session \( s \) receives from the Internet. Note that the destination node \( d_s \) does not need to maintain a data queue for its own service since data will be directly passed on to the upper layers.

Besides, at the source and destination nodes, we have the
following routing constraints:

\[
\sum_{j \in N, j \neq i} l^s_{ij}(t) = 0, \quad \text{if } i = s(t), s \in S, \quad (16)
\]
\[
\sum_{j \in N, j \neq i} l^u_{ij}(t) = 0, \quad \text{if } i = d_s, s \in S, \quad (17)
\]
\[
\sum_{j \in N, j \neq i} l^v_{ij}(t) = v_s(t), \quad \text{if } i = d_s, s \in S, \quad (18)
\]
\[
\sum_{i \in B} l^v_{is}(t) = 1. \quad (19)
\]

Constraints (16) and (17) indicate that there is no incoming data and outgoing data at the source node and the destination node for service session \(s\), respectively. Constraint (18) models the throughput requirement of service session \(s\), where \(v_s(t)\) is the number of packets required by session \(s\). Constraint (19) indicates that there is only one source base station for session \(s\) in any time slot \(t\).

### 4.2 Link Layer Design

Next, we illustrate the channel allocation and link scheduling constraints on data transmissions.

Assume that band \(m\) is available at both node \(i\) and node \(j\), i.e., \(m \in M_i \cap M_j\). We denote

\[
\alpha_{ij}^m(t) = \begin{cases} 
1, & \text{if node } i \text{ transmits to node } j \text{ using band } m \\
0, & \text{otherwise}.
\end{cases}
\]

Since a node is not able to transmit to or receive from multiple nodes on the same frequency band in a single time slot, we have

\[
\sum_{j \in N, j \neq i} \alpha_{ij}^m(t) \leq 1, \quad \text{and} \quad \sum_{i \in N, i \neq j} \alpha_{ij}^m(t) \leq 1. \quad (20)
\]

Besides, a node cannot use the same frequency band for transmission and reception simultaneously, due to “self-interference” at physical layer, i.e.,

\[
\sum_{i \in N, i \neq j} \alpha_{ij}^m(t) + \sum_{q \in N, q \neq j} \alpha_{jq}^m(t) \leq 1. \quad (21)
\]

Moreover, we consider that each node is only equipped with one single radio, which means that each node can only transmit or receive on one frequency band at a time. Thus, we have

\[
\sum_{m \in M, m \neq j} \sum_{i \in N, j \neq i} \alpha_{ij}^m(t) + \sum_{m \in M, q \neq j} \alpha_{jq}^m(t) \leq 1. \quad (22)
\]

Notice that (20) and (21) will hold whenever (22) holds.

Recall that in (2), \(E_{i}^{TX}(t)\) is node \(i\)'s consumed energy for serving its traffic. Thus, it can be calculated as follows:

\[
E_{i}^{TX}(t) = \sum_{m \in M, j \neq i} \sum_{j \neq i} \sum_{j \neq i} \alpha_{ij}^m(t)P_i^{mij}(t) \Delta t + \sum_{m \in M, j \neq i} \sum_{j \neq i} \alpha_{ij}^m(t)P_i^{recv} \Delta t, \quad (23)
\]

where node \(i\)'s receiving power, i.e., \(P_i^{recv}\), is a constant, and \(\Delta t\) is the time duration of one time slot.

In addition to the above constraints at a certain node, there are also constraints due to potential interference among different nodes. In particular, according to the Physical Model discussed in Section 3.2, if node \(i\) uses a frequency band \(m\) for transmitting data to another node, the cumulative interference from all the other nodes transmitting on \(m\) at the same time plus the noise power level should be low enough so that the SINR of node \(i\)'s transmission is above the threshold \(\Gamma\), i.e.,

\[
g_{ij}P_{ij}^m(t) \geq \Gamma(\eta_i W^m(t) + \sum_{k \neq i, v \neq j} g_{kj}P_{kv}^m(t)).
\]

Rewriting the above expression in the form of a constraint that accommodates all the link-band pairs in the network, we have

\[
g_{ij}P_{ij}^m(t)\alpha_{ij}^m(t) + M_i^m(1 - \alpha_{ij}^m(t)) \geq \Gamma(\eta_i W^m(t) + \sum_{k \neq i, v \neq j} g_{kj}P_{kv}^m(t)\alpha_{kv}^m(t)), \quad (24)
\]

where \(M_i^m(1 - \alpha_{ij}^m(t))\) is set as the sum of interferences from all the other nodes and the noise, i.e.,

\[
M_i^m(1 - \alpha_{ij}^m(t)) = \Gamma(\eta_i W^m(t) + \sum_{k \neq i, v \neq j} g_{kj}P_{kv}^{max}).
\]

Moreover, the flow rate over link \((i, j)\) should satisfy the following inequality, i.e.,

\[
\delta \sum_{s \in S} l_{ij}^m(t) \leq \sum_{m \in M, i \cap M_j} c_{ij}^m(t)\alpha_{ij}^m(t) \Delta t \quad (25)
\]

where \(\delta\) is the number of bits per packet. (25) indicates that the total number of bits transmitted on a link during one time slot cannot exceed the link’s capacity multiplied by the duration of one time slot.

### 4.3 Offline Energy-Source-Aware Cost Minimization

Our objective is to minimize the time-averaged expected energy cost of the cellular service provider given the routing, link scheduling and energy capabilities, while guaranteeing the strong stability of the network. Thus, the offline energy-source-aware cost optimization problem can be formulated as follows:

\[
P_1: \text{Minimize } \psi = \lim_{T \to \infty} \frac{1}{T} \sum_{t=0}^{T-1} E[f(P(t))],
\]

s.t. Constraints (9)-(14), (16)-(19), (22)-(25), \(\forall t \geq 0\)

\(Q(t)\) and \(x(t)\) are strongly stable. \( (26)\)

where \(Q(t) = \{Q_i^s(t), \forall i \in N, s \in S\}\) and \(x(t) = \{x_i(t), \forall i \in N\}\). We denote the optimal result of \(P_1\) by \(\psi_{\hat{P}_1}\).

We can see that without the constraint (26), \(P_1\) is a time-coupling stochastic Mixed-Integer Non-Linear Programming (MINLP) problem, which is already prohibitively expensive to solve. Previous approaches usually solve such problems based on Dynamic Programming and suffer from the “curse of dimensionality” problem [8]. They also require detailed statistical information on the random variables in the problem, i.e., the available spectrums, and output of renewable energy resources at each node, which may be difficult to obtain in practice. In addition, the constraint (26) makes \(P_1\) an even more complicated problem. Next, we will reformulate this problem into an online optimization problem using Lyapunov optimization to break the time coupling in \(P_1\) and find a feasible solution to it only based on the current network states.

5 ONLINE ENERGY-SOURCE-AWARE COST MINIMIZATION

In this section, we exploit Lyapunov optimization techniques to design an online energy-source-aware algorithm to solve the energy cost minimization problem without requiring any priori knowledge of the network parameters.

Before we delve into the details, we first reformulate P1 into an equivalent offline optimization problem P2. In particular, summing the inequality (25) over all $t \in \{0, 1, ..., T - 1\}$, and taking expectation and limitation on both sides, we get

$$
\lim_{T \to \infty} \frac{1}{T} \sum_{t=0}^{T-1} E[\delta \sum_{s \in S} l_{ij}^s(t)] 
\leq \lim_{T \to \infty} \frac{1}{T} \sum_{t=0}^{T-1} E[\sum_{m \in M_i \cap M_j} c_{ij}^m \alpha_m(t) \Delta t].
$$

(27)

Thus, we define $\overline{P}$ as

$$
\overline{P} = \lim_{T \to \infty} \frac{1}{T} \sum_{t=0}^{T-1} E[f(P(t)) - \lambda \sum_{s \in S} \sum_{t \in \mathcal{E}} k_s(t) \cdot 1_{i=s_i}(t)],
$$

where $\lambda$ is a coefficient that can be determined by the system operator. We then formulate the following optimization problem P2:

**P2:** Minimize $\psi = \overline{P}$

s.t. Constraints (9)-(14), (16)-(19), (22)-(27), $\forall t \geq 0$.

We denote the optimal result of P2 by $\psi^{P2}$. We formulate P2 in such a way to help ensure the strong stability of the network, which will be clear later. Besides, note that similar to P1, P2 is also a time-coupling MINLP problem. In what follows, we will formulate a drift-plus-penalty problem based on P2, which we call P3.

5.1 Modeling Virtual Queues

In order to guarantee that all queues in the network are stable, we introduce virtual queues as follows. Consider a virtual queue $G_{ij}(t)$ at node $i$ for each of its one-hop neighbor $j$ with the following queueing law:

$$
G_{ij}(t + 1) = \max \left\{ G_{ij}(t) - \frac{1}{\delta} \sum_{m \in M_i \cap M_j} c_{ij}^m \alpha_m(t) \Delta t, 0 \right\}
+ \sum_{s \in S} l_{ij}^s(t).
$$

(28)

This virtual queue can be understood as the link-layer buffer for link $(i, j)$. The queue backlog $G_{ij}(t)$ represents the total number of packets stored at node $i$ to be transmitted to node $j$ at the beginning of time slot $t^1$.

For queue $G_{ij}(t)$, we have

$$
\frac{1}{\delta} \sum_{m \in M_i \cap M_j} c_{ij}^m \alpha_m(t) \Delta t - \sum_{s \in S} l_{ij}^s(t)
\leq \frac{1}{\delta} \sum_{m \in M_i \cap M_j} c_{ij}^m \alpha_m(t) \Delta t
\leq \frac{1}{\delta} \sum_{m \in M_i \cap M_j} c_{ij}^m \alpha_m(t) \Delta t
$$

(29)

where $\frac{1}{\delta} \sum_{m \in M_i \cap M_j} c_{ij}^m \alpha_m(t) \Delta t$ is a constant. Therefore, if we can guarantee the strong stability of this queue, we can ensure its rate stability, i.e., constraint (27), according to Theorem 2. Besides, the virtual queue backlog is always nonnegative according to the queueing law (28).

Instead of utilizing $G_{ij}(t)$ directly, we build another virtual queue $H_{ij}(t) = \beta G_{ij}(t)$, where $\beta = \max_{i,j \in N, j \neq i} \{ \frac{1}{\delta} c_{ij}^m \alpha_m(t) \Delta t \}$. Thus, the queueing law of $H_{ij}(t)$ is

$$
H_{ij}(t + 1) = \max \left\{ H_{ij}(t) - \frac{\beta}{\delta} \sum_{m \in M_i \cap M_j} c_{ij}^m \alpha_m(t) \Delta t, 0 \right\}
+ \beta \sum_{s \in S} l_{ij}^s(t).
$$

(30)

Note that the strong stability of $H_{ij}(t)$ implies the strong stability of $G_{ij}(t)$, and hence (27) would directly follow.

5.2 Reformulation of Dynamic Energy Cost Minimization Using Lyapunov Optimization

We first define a shifted energy level $z_i(t)$ for any node $i \in N$ to better control its energy storage unit, i.e.,

$$
z_i(t) = x_i(t) - V \gamma_{\max} - d_i^\max.
$$

where $\gamma_{\max}$ is the maximum first-order derivative of $f(P(t))$ with respect to $P(t)$, and $V$ is a positive constant to be defined later. Thus, according to (4), $z_i(t)$ is updated following the queueing law below:

$$
z_i(t + 1) = z_i(t) + c_i(t) - d_i(t).
$$

(31)

Note that based on constraint (10), we have:

$$-V \gamma_{\max} - d_i^\max \leq z_i(t) \leq a_i^\max - V \gamma_{\max} - d_i^\max
$$

(32)

Next, we define a Lyapunov function [9] as

$$
L(\Theta(t)) = \frac{1}{2} \sum_{s \in S} \sum_{i \in N} (Q_i^s(t))^2 + \sum_{i \in N} \sum_{j \in N, j \neq i} (H_{ij}(t))^2 + \sum_{i \in N} (z_i(t))^2
$$

where $\Theta(t) = \{Q(t), H(t), z(t)\}$. We assume $Q(0) = 0$, $H(0) = 0$, and $z(0) = 0$. This function represents a scalar measure of queues in the system. $L(\Theta(t))$ being small indicates that all queue backlogs are low, while $L(\Theta(t))$ being large implies that at least one queue backlog is high. Meanwhile, its one-slot conditional Lyapunov drift is defined as

$$
\Delta(\Theta(t)) \triangleq E[L(\Theta(t + 1)) - L(\Theta(t))|\Theta(t)].
$$

(33)

In order to minimize the long-term time-averaged expected total cost of energy from UC, instead of directly minimizing $\Delta(\Theta(t))$, we intend to minimize the upper bound of the drift-plus-penalty function, which is defined as:

$$
\Delta(\Theta(t)) + V E[f(P(t)) - \lambda \sum_{s \in S \in B} k_s(t) \cdot 1_{i=s_i}(t)|\Theta(t)]
$$

where $V \geq 0$ is a constant that represents the weight on how much we emphasize on the energy cost minimization. Such a scheduling decision can be explained as follows:
we want to make $\Delta(\Theta(t))$ small to push queue backlog towards a lower congestion state, but we also want to make $(f(P(t)) - \lambda \sum_{s \in S} \sum_{i \in B} k_s(t) \cdot 1_{i=s(t)}$ small in each time slot so that the energy cost can be low.

We can have the following lemma.

**Lemma 1:** Given $\Delta(\Theta(t))$ defined in (33), we have

$$\Delta(\Theta(t)) + V \mathbb{E}[f(P(t)) - \lambda \sum_{s \in S} \sum_{i \in B} k_s(t) \cdot 1_{i=s(t)}] \Theta(t) \leq B + \Psi_1(t) + \Psi_2(t) + \Psi_3(t) + \Psi_4(t),$$

where $B$ is a constant, i.e.,

$$B = \frac{1}{2} \sum_{s \in S} \sum_{i \in N} \left( \left( \max_{j \in N, j \neq i} \left( \frac{1}{c_{ij}^\alpha} \right) \right)^2 
+ \left( \max_{j \in N, j \neq i} \left( \frac{1}{c_{ij}^\alpha} \right) + \frac{1}{t_{ij}^\max} \right)^2 
+ \sum_{i \in N, j \in N, j \neq i} \left[ \frac{1}{c_{ij}^\alpha} \left( \frac{1}{c_{ij}^\alpha} \right)^2 \right] 
+ \sum_{i \in N} \max \left\{ \left( c_{ij}^\alpha \right)^2, \left( d_{ij}^\alpha \right)^2 \right\} \right)$$

$$\Psi_1(t) \text{ is only related to the link scheduling variables } \alpha_{ij}(t) \text{'s, i.e.,}$$

$$\Psi_1(t) = -\frac{\beta}{\delta} \mathbb{E} \left[ \sum_{i \in N, j \in N, j \neq i} \left( H_{ij}(t) \sum_{m \in M_i \cap M_j} c_{ij}^m(t) a_{ij}(t) \right) \cdot \Delta(t) \right] \Theta(t),$$

$$\Psi_2(t) \text{ is related to the resource allocation variables } k_s(t) \text{ and } 1_{i=s(t)} \text{'s, i.e.,}$$

$$\Psi_2(t) = \mathbb{E} \left[ \sum_{s \in S} \sum_{i \in B} \left( (Q^i_s(t) - \lambda V) (k_s(t) \cdot 1_{i=s(t)}) \right) \right] \Theta(t),$$

$$\Psi_3(t) \text{ is only related to the routing variables } l_{ij}(t) \text{'s, i.e.,}$$

$$\Psi_3(t) = \mathbb{E} \left[ \sum_{s \in S} \sum_{i \in N} Q^i_s(t) \left( \sum_{j \in N, j \neq i} l_{ij}(t) - \sum_{j \in N, j \neq i} l_{ij}(t) \right) \right] \Theta(t) + \mathbb{E} \left[ \sum_{i \in N, j \in N, j \neq i} \left( \beta H_{ij}(t) \sum_{s \in S} l_{ij}(t) \right) \Theta(t) \right],$$

$$\text{and } \Psi_4(t) \text{ is related to the energy management variables } c_{ij}(t),$$

$$\Psi_4(t) = \mathbb{E} \left[ \sum_{i \in N} \left( z_i(t) (c_i(t) - d_i(t)) \right) \right] \Theta(t)$$

$$+ \mathbb{E} \left[ f(P(t)) \right] \Theta(t).$$

**Proof:** Note that $\forall x, y, z$ with $x \geq 0$, $0 \leq y \leq y_{\max}$, $0 \leq z \leq z_{\max}$, we have

$$\max \{ x - y, 0 \} + z \geq x^2 + y^2 + z^2 + 2x(z - y)$$

$$\leq x^2 + y_{\max}^2 + z_{\max}^2 + 2x(z - y).$$

Due to (25), we know that

$$\sum_{i \in N, j \neq i} l_{ij}(t) \leq \frac{1}{\delta} \sum_{i \in N, j \neq i} m_{i \in M_i \cap M_j} c_{ij}^m(t) a_{ij}(t) \Delta(t).$$

Denote by $c_{ij}^\max$ the maximum possible link capacity of link $(i, j)$. Since $c_{ij}^m(t)$ depends on $d(i, j)$ and $W_{\text{max}}(t)$, among which $d(i, j)$ is constant, then $c_{ij}^\max$ is determined by $W_{\text{max}}$, i.e., the maximum bandwidth that the channels available on link $(i, j)$

can have. Thus, according to (22), i.e., one node can transmit to at most one neighbor on at most one band at a time, we can get

$$\sum_{j \in N, j \neq i} l_{ij}(t) \leq \max_{j \in N, j \neq i} \left( \frac{1}{c_{ij}^\alpha} \right) \Delta(t).$$

Similarly, we also have

$$\sum_{j \in N, j \neq i} l_{ij}(t) \leq \max_{j \in N, j \neq i} \frac{1}{c_{ij}^\alpha} \Delta(t).$$

Besides, we have $k_s(t) \leq K_{\text{max}}$. Thus, based on (15), (30), (31) and (36), we can obtain the following inequalities:

$$(Q^i_s(t + 1))^2 \leq (Q^i_s(t))^2 + \left( \max_{j \in N, j \neq i} \left( \frac{1}{c_{ij}^\alpha} \right) \Delta(t) \right)^2$$

$$+ \left( \max_{j \in N, j \neq i} \left( \frac{1}{c_{ij}^\alpha} \right) + K_{\text{max}} \cdot 1_{i=s(t)} \right)^2$$

$$+ 2Q^i_s(t) \cdot \left( \sum_{j \in N, j \neq i} l_{ij}(t) \right)$$

$$+ k_s(t) \cdot 1_{i=s(t)} - \sum_{j \in N, j \neq i} l_{ij}(t) \right)$$

$$(H_{ij}(t + 1))^2 \leq (H_{ij}(t))^2 + 2 \left( \frac{\beta}{\delta} \right) (\Delta(t))^2 + 2H_{ij}(t) \cdot$$

$$\left( \sum_{s \in S} \beta l_{ij}(t) - \frac{\beta}{\delta} \sum_{m \in M_i \cap M_j} c_{ij}^m(t) a_{ij}(t) \Delta(t) \right)$$

$$(z_i(t + 1))^2 \leq (z_i(t))^2 + \max \left\{ (c_{ij}^\alpha)^2, (d_{ij}^\alpha)^2 \right\}$$

$$+ 2z_i(t) (c_i(t) - d_i(t))$$

Applying these inequalities to the drift-plus-penalty function, we have

$$\Delta(\Theta(t)) + V \mathbb{E}[f(P(t)) - \lambda \sum_{s \in S} \sum_{i \in B} k_s(t) \cdot 1_{i=s(t)}] \Theta(t) \leq \frac{1}{2} \sum_{s \in S} \sum_{i \in N} \left( \left( \max_{j \in N, j \neq i} \left( \frac{1}{c_{ij}^\alpha} \right) \right)^2 \right)$$

$$+ \left( \max_{j \in N, j \neq i} \left( \frac{1}{c_{ij}^\alpha} \right) + K_{\text{max}} \cdot 1_{i=s(t)} \right)^2$$

$$+ \sum_{i \in N} \max \left\{ (c_{ij}^\alpha)^2, (d_{ij}^\alpha)^2 \right\}$$

$$+ \left( \sum_{s \in S} \beta l_{ij}(t) - \frac{\beta}{\delta} \sum_{m \in M_i \cap M_j} c_{ij}^m(t) a_{ij}(t) \Delta(t) \right)$$

$$+ \sum_{i \in N} \max \left\{ (c_{ij}^\alpha)^2, (d_{ij}^\alpha)^2 \right\}$$

$$+ \left( \sum_{i \in N} \sum_{j \in N, j \neq i} \left( H_{ij}(t) \sum_{s \in S} l_{ij}(t) + k_s(t) \cdot 1_{i=s(t)} \right) \right)$$

$$+ \left( \sum_{i \in N} \sum_{j \in N, j \neq i} \left( H_{ij}(t) \sum_{s \in S} l_{ij}(t) \right) \right)$$

$$+ \left( \sum_{i \in N} \sum_{j \in N, j \neq i} \left( z_i(t) (c_i(t) - d_i(t)) \right) \right)$$

$$+ \left( \sum_{i \in N} \sum_{j \in N, j \neq i} \left( z_i(t) (c_i(t) - d_i(t)) \right) \right)$$

Thus, Lemma 1 directly follows. □

Based on the drift-plus-penalty framework, our objective is to minimize the right-hand-side of (34), and hence to minimize $\Psi_1(t) + \Psi_2(t) + \Psi_3(t) + \Psi_4(t)$ since $B$ is a constant, given the current system status $\Theta(t) = \{Q(t), H(t), z(t)\}$ in each time slot. We now use the concept of opportunistically minimizing
an expectation [9], which is to minimize:
\[ \Psi_1(t) = -\frac{\beta}{\delta} \sum_{i\in N} \sum_{j \in N, j \neq i} (H_{ij}(t) \cdot \Delta t) \]
\[ \cdot \sum_{m \in \mathcal{M}_i \cap \mathcal{M}_j} c_{ij}^m(t) \alpha_{ij}^m(t) \Delta t \]
\[ \Psi_2(t) = \sum_{s \in S} \sum_{i \in B} \left( (Q_1^s(t) - \lambda V)(k_s(t) \cdot 1_{i=s_i(t)}) \right) \]
\[ \Psi_3(t) = \sum_{s \in S} \sum_{i \in N} Q_1^s(t) \left( \sum_{j \in N, j \neq i} l_{ij}^s(t) - \sum_{j \in N, j \neq i} l_{ij}^s(t) \right) \]
\[ + \sum_{i \in N} \sum_{j \in N, j \neq i} (H_{ij}(t) \beta l_{ij}^s(t)) \]
\[ \Psi_4(t) = \sum_{i \in N} \left( \hat{z}_i(t)(c_i(t) - d_i(t)) \right) + V f(P(t)). \]

Therefore, the problem of online energy-source-aware cost minimization can be formulated as follows:

\[ \textbf{P3}: \quad \text{Minimize} \quad \Psi_1(t) + \Psi_2(t) + \Psi_3(t) + \Psi_4(t) \]
\[ \text{s.t.} \quad \text{Constraints (9), (11)-(14), (16)-(19), (22)-(25),} \]
\[ \Theta(t) \text{ is strongly stable.} \]

Note that the constraint (27) has been left out in \textbf{P3} (compared to \textbf{P2}) since it can be guaranteed if \( H(t) \) is strongly stable as mentioned before.

5.3 A Decomposition Based Approximation Algorithm

In the following we decompose \textbf{P3} into four subproblems (from S1 to S4) and solve them respectively. The intuition is that since each subproblem has fewer variables compared with that in \textbf{P3} and can be solved easily, by solving the subproblems one by one, the later subproblems can treat the variables that have been solved in previous subproblems as constants. Consequently, we can obtain a feasible solution to \textbf{P3}.

5.3.1 Link Scheduling

First, we minimize \( \hat{\Psi}_1(t) \) by finding the optimal link scheduling policy, i.e., determining the variables \( \alpha_{ij}^m(t) \)'s (\( \forall i, j \in N, j \neq i, m \in \mathcal{M}_i \cap \mathcal{M}_j \)), as follows:

\[ \textbf{S1: Minimize} \quad \hat{\Psi}_1(t) \]
\[ \text{s.t.} \quad \text{Constraint (22).} \]

Since the variables \( \alpha_{ij}^m(t) \)'s can only take value of 0 or 1, the above subproblem is a Binary Integer Programming (BIP) problem. In the following, based on the similar ideas in [43], [46], we propose a heuristic greedy scheme called the sequential-fix (SF) algorithm to find a suboptimal solution to this problem, the solution of which can be obtained in polynomial time. The main idea of SF is to fix the binary variables \( \alpha_{ij}^m(t) \)'s sequentially through a series of relaxed linear programming problems. Specifically, we first set \( \alpha_{ij}^m(t) \)'s to 0 if \( H_{ij}(t) = 0 \), remove all the terms associated with such \( \alpha_{ij}^m(t) \)'s from the objective function, and eliminate the related constraints in (22). Then, in each iteration, we first relax all the 0-1 integer constraints on \( \alpha_{ij}^m(t) \)'s to \( 0 \leq \alpha_{ij}^m(t) \leq 1 \) to transform the problem to a linear programming (LP) problem. Then, we solve this LP to obtain an optimal solution with each \( \alpha_{ij}^m(t) \) being between 0 and 1. Among all the values, we set the largest \( \alpha_{ij}^m(t) \) to 1. After that, based on the constraint (22), we can fix \( \alpha_{ij}^m(t) \) \& \( \alpha_{ij}^m(t) \) \& \( \alpha_{ij}^m(t) \) for any \( n \in \mathcal{M}_j \) and \( p, q \in \mathcal{N} \). Besides, if the result includes several \( \alpha_{ij}^m(t) \)'s with the value of 1, we can set those \( \alpha_{ij}^m(t) \)'s to 1 and perform an additional fixing for the largest fractional variable in the current iteration as illustrated above. Having fixed some \( \alpha_{ij}^m(t) \)'s in the first iteration, we remove all the terms associated with those already fixed \( \alpha_{ij}^m(t) \)'s from the objective function, eliminate the related constraints in (22), and update the problem to a new one for the next iteration. The iteration continues until we fix all \( \alpha_{ij}^m(t) \)'s to be either 0 or 1.

5.3.2 Resource Allocation

Second, we minimize \( \hat{\Psi}_2(t) \) by finding the source base station for each service session \( s \) (\( s \in S \)) and determining its incoming packet rate \( k_s(t) \), i.e.,

\[ \textbf{S2: Minimize} \quad \hat{\Psi}_2(t) \]
\[ \text{s.t.} \quad \text{Constraints (19).} \]

We develop the following search algorithm to locally find a resource allocation policy. Specifically, at the beginning of each time slot, given the current queue backlogs \( Q_1^s(t) \)'s (\( \forall i \in B \)) for each service session \( s \), we find the base station with the smallest \( Q_1^s(t) \) and choose it as the source base station. If there are multiple variables with the same smallest queue backlog, we randomly pick one of them as the source base station. After that, we can determine the source node’s incoming packet rate as follows:

\[ k_s(t) = \begin{cases} 
K_{max}^s, \quad & \text{if } Q_{s_s(t)}^s - \lambda V < 0 \\
0, \quad & \text{otherwise.}
\end{cases} \]

5.3.3 Routing

Third, after reorganizing \( \hat{\Psi}_3(t) \), we minimize it by finding the optimal routing policy, i.e., determining the variables \( l_{ij}^s(t) \)'s (\( \forall s \in S, i, j \in N, j \neq i \)), as follows:

\[ \textbf{S3: Minimize} \quad \sum_{s \in S} \sum_{i \in N} \sum_{j \in N, j \neq i} (-Q_1^s(t) + Q_3^s(t) + \beta H_{ij}(t)) \cdot l_{ij}^s(t) \]
\[ \text{s.t.} \quad \text{Constraints (16)-(18), (25).} \]

We can see that \textbf{S3} is an Integer Linear Programming (ILP) problem with the only variables being \( l_{ij}^s(t) \)'s. We notice that the total flow rate \( \sum_{s \in S} l_{ij}^s(t) \) over link \( (i, j) \) does not affect the flow rates over other links \( \{(p, q) | p \neq i \land q \neq j \} \), and only depends on its link capacity according to the constraint (25). Besides, the objective function of \textbf{S3} can be viewed as a weighted sum of the variables \( l_{ij}^s(t) \)'s. Therefore, we can determine the flow rate over any link \( (i, j) \) at node \( i \) locally, based on its current queue backlogs \( Q_3^s(t) \) and \( H_{ij}(t) \), and the queue backlogs of node \( j \), i.e., \( Q_2^s(t) \). In the following, we will propose an algorithm to obtain the optimal solution for \( l_{ij}^s(t) \)'s.
In particular, we first set the variables $l_{ij}^s$’s ($\forall ij \in S, s \in S$) and those ($\forall i = d_s, j \in N \setminus \{i\}, s \in S$) to 0 according to constraints (16) and (17). Besides, if a node $j = d_s$ ($s \in S$) in time slot $t$, then the variable $l_{ij}^s$ ($\forall i \in N \setminus \{j\}$) with the smallest coefficient in the objective function of $S3$ is set to $v_s(t)$ due to constraint (18). In all the other cases, in order to minimize the objective function, node $i$ also sets the variables $l_{ij}^s$’s ($\forall ij \in N, j \neq i, s \in S$) to 0 if their coefficients are non-negative. Otherwise, for any $l_{ij}^s$’s ($s \in S$) over link $(i,j)$, node $i$ sets the variable with the smallest coefficient to $\frac{1}{\delta_s} \sum_{m \in \mathcal{M}_j} c_{ij}^m(t) \alpha_{ij}^m(t) \Delta t$ while the rest to 0, due to the constraint (25). The intuition is that by doing so, the link $(i,j)$ can be fully utilized while minimizing $S3$. Besides, if there are variables $l_{ij}^s$’s with the same smallest coefficient on link $(i,j)$, node $i$ randomly picks one of them and sets it to $\frac{1}{\delta_s} \sum_{m \in \mathcal{M}_j} c_{ij}^m(t) \alpha_{ij}^m(t) \Delta t$ while the rest to 0. Note that $\alpha_{ij}^m(t)$’s are known from the link scheduling optimization problem $S1$. It is possible that $\frac{1}{\delta_s} \sum_{m \in \mathcal{M}_j} c_{ij}^m(t) \alpha_{ij}^m(t) \Delta t$ is equal to 0 if $\sum_{m \in \mathcal{M}_j} c_{ij}^m(t) \alpha_{ij}^m(t) = 0$. Then, the corresponding variable $l_{ij}^s$ is also equal to 0.

5.3.4 Energy Management

Fourth, in order to minimize $\hat{\Psi}_4(t)$, we try to find the optimal energy management for all $i \in N$, i.e., determining the variables $P_{ij}^m(t)$’s, $c_i^x(t)$’s, $c_i^s(t)$’s, $r_i(t)$’s, $d_i(t)$’s, and $g_i(t)$’s. This problem can be formulated as follows:

**S4:** Minimize $\hat{\Psi}_4(t)$

s.t. Constraints (9), (11)-(14), (24).

Notice that $S4$ is a convex optimization problem, which can be easily solved, e.g., using CPLEX, given the system states and shifted energy levels $z_i(t)$.

In summary, in each time slot, the online energy-source-aware minimization problem $P3$ can be solved after $S1$, $S2$, $S3$ and $S4$ are solved. The queues $Q(t)$, $H(t)$ and $\pi(t)$ are then updated in each time slot according to the queuing laws (15), (30), and (31), respectively. We will show in the next section that all queues are strongly stable, and particularly, $z_i(t)$ are within its limits, i.e., (32). We denote the corresponding time-averaged expected total energy cost by $\psi_{P3}$.

6 PERFORMANCE ANALYSIS

In this section, we first prove that the proposed approximation algorithm can guarantee the network strong stability. Then, we derive both the lower and upper bounds on the optimal result of $P1$.

6.1 Network Strong Stability

Our proposed algorithm finds a solution to $P3$ which satisfies the constraints (9), (11)-(14), (16)-(19), (22)-(25). We can have the following theorem.

**Theorem 3:** Our proposed approximation algorithm guarantees that the queues $Q(t)$, $H(t)$ and $\pi(t)$ are all strongly stable, and particularly, $z_i(t)$ are within its limits, i.e., (32).

**Proof:** First, we demonstrate the strong stability of $Q(t)$ by considering an arbitrary queue $Q_i(t)$. Specifically, we prove by induction that $Q_i(t) \leq \lambda V + K_{max}^s$.

When $t = 0$, we have $Q_i^s(0) = 0 < \lambda V + K_{max}^s$.

Assume that we have $Q_i^s(t) \leq \lambda V + K_{max}^s$ in time slot $t$ ($t \geq 0$). Then, we consider the following two cases to prove the stability of $Q_i^s(t)$.

1) if $i = s_s(t)$: According to the queuing law of $Q_i(t)$, we have

$$Q_i^s(t + 1) = \max\{Q_i^s(t) - \sum_{j \in N, j \neq s_s} l_{ij}^s(t), 0\} + k_s(t).$$

Based on the derived solution to the subproblem $S2$, we have the following two subcases:

- If $Q_i^s(t) \geq \lambda V$, according to the optimal solution to $S2$, we know that $k_s(t) = 0$. Thus, we have $Q_i^s(t + 1) \leq Q_i^s(t) \leq \lambda V + K_{max}^s$.

- If $Q_i^s(t) < \lambda V$, according to the optimal solution to $S3$, we get that $k_s(t) = K_{max}^s$. Following (45), we have $Q_i^s(t + 1) \leq Q_i^s(t) + K_{max}^s \leq \lambda V + K_{max}^s$.

Therefore, we have $Q_i^s(t) \leq \lambda V + K_{max}^s$.

2) if $i \neq s_s(t)$ and $i \neq d_s$: We then explore the stability of $Q_i(t)$ when $i \neq s_s(t)$ and $i \neq d_s$, whose queuing law is:

$$Q_i(t + 1) = \max\{Q_i(t) - \sum_{j \in N, j \neq i} l_{ij}^s(t), 0\} + \sum_{j \in N, j \neq i} l_{ij}^s(t).$$

Since only one neighboring node can transmit to node $i$ in time slot $t$, we denote it by $j$. Consider the coefficient in front of $l_{ij}^s(t)$ in the objective function of $S3$.

- If $Q_i(t) < Q_i^s(t) - \beta H_{ji}(t)$, according to (46), we have $Q_i^s(t + 1) \leq Q_i^s(t) + l_{ij}^s(t) < Q_i(t) - \beta H_{ji}(t) + l_{ij}^s(t) \leq Q_i^s(t) \leq \lambda V + K_{max}^s$.

The third inequality above can be proved in the following two cases.

- If $H_{ji}(t) = 0$, according to the solution to $S1$, we can know that $\alpha_{ji}^m(t) = 0 \ \forall m \in \mathcal{M}_j \cap \mathcal{M}_i$, and hence $l_{ij}^s(t) = 0$. Thus, the inequality holds.

- If $H_{ji}(t) \geq 1$, we have $\beta H_{ji}(t) \geq l_{ij}^s(t)$, as $l_{ij}^s(t) \leq \max_{s \in S} \{\sum_{m \in \mathcal{M}_j} c_{ij}^m(t) \Delta t\} = \beta$ as defined before.

- If $Q_i^s(t) \geq Q_i^s(t) - \beta H_{ji}(t)$, according to our proposed solution to $S3$, we know that $l_{ij}^s(t) = 0$. Following (46), we have $Q_i^s(t + 1) \leq Q_i^s(t) \leq \lambda V + K_{max}^s$.

Therefore, we also have $Q_i^s(t) \leq \lambda V + K_{max}^s$.

Note that the destination node $d_s$ does not need to maintain a data queue since data will be directly passed on to the upper layers. Consequently, based on the above results, we can see that an arbitrary queue $Q_i^s(t)$ is finite in any time slot. Thus, $Q_i(t)$ is strongly stable by Definition 2.

Second, we prove the strong stability of $H(t)$, and particularly,

$$H_{ij}(t) \leq \beta \cdot \max_{0 \leq k < t} \sum_{s \in S} l_{ij}^s(k).$$ (47)
for any $i, j \in \mathcal{N}$, by induction. We consider an arbitrary queue $H_{ij}(t)$.

When $t = 0$, we have $H_{ij}(0) = 0$, and hence (47) holds.

When $t = 1$, we have $H_{ij}(1) = \sum_{s \in S} l^i_{jk}(0)$ according to the queueing law (30), and (47) holds.

Assume (47) holds in time $t$, i.e., $H_{ij}(t) \leq \beta \cdot \max_{0 \leq k \leq t} \sum_{s \in S} l^i_{jk}(k)$. Then, at the beginning of time slot $t + 1$, we have

$$H_{ij}(t + 1) = \max \{ H_{ij}(t) - \beta \cdot \delta \sum_{m \in \mathcal{M}_i \cap \mathcal{M}_j} c^m_{ij}(t) a^m_{ij}(t) \Delta t, 0 \}$$

$$+ \beta \sum_{s \in S} l^s_{ij}(t).$$

If $H_{ij}(t) > \frac{\beta}{\delta} \sum_{m \in \mathcal{M}_i \cap \mathcal{M}_j} c^m_{ij}(t) a^m_{ij}(t) \Delta t$, with inequality (25), we have

$$H_{ij}(t + 1) \leq H_{ij}(t) \leq \beta \cdot \max_{0 \leq k \leq t} \sum_{s \in S} l^s_{ij}(k)$$

$$\leq \beta \cdot \max_{0 \leq k \leq t + 1} \sum_{s \in S} l^s_{ij}(k).$$

If $H_{ij}(t) \leq \frac{\beta}{\delta} \sum_{m \in \mathcal{M}_i \cap \mathcal{M}_j} c^m_{ij}(t) a^m_{ij}(t) \Delta t$, then

$$H_{ij}(t + 1) = \sum_{s \in S} l^s_{ij}(t) \leq \beta \cdot \max_{0 \leq k \leq t + 1} \sum_{s \in S} l^s_{ij}(k).$$

Therefore, (47) holds when $t = t + 1$ as well.

Since $\sum_{s \in S} l^s_{ij}(k) \leq \frac{\beta}{\delta} c^i_{ij} \Delta t$, we have that $H_{ij}(t) \leq \frac{\beta}{\delta} c^i_{ij} \Delta t$ and hence always finite and strongly stable.

Third, we prove the strong stability of $z(t)$, i.e., (32), which directly follows if the strong stability of $x(t)$, i.e., (10), holds. Firstly, we define the maximum value of $V$ as:

$$V^\text{max} = \min_ {i \in \mathcal{N}} \frac{x^i_{\text{max}} - c^i_{\text{max}} - d^i_{\text{max}}}{\gamma^\text{max}}.$$ 

Assume that for arbitrary node $i$, (10) holds in time slot $t$. Then we consider three cases when in the time slot $t + 1$.

- If $0 \leq x_i(t) < d^i_{\text{max}}$. Recall that $c_i(t) = \omega_i(t)c^2_i(t) + c^i_{\text{max}}$. In this case, the partial derivative of the objective function of $S4$, i.e., $\hat{\Psi}_4(t)$, with respect to $c^i_{\text{max}}$, is

$$\frac{\partial \hat{\Psi}_4(t)}{\partial c^i_{\text{max}}} = z_i(t) + V \frac{\partial f(P(t))}{\partial c^i_{\text{max}}}$$

$$\leq x_i(t) - V^{\gamma^\text{max}} - d^i_{\text{max}} + 0$$

$$< 0.$$ 

Thus, by solving $S4$, i.e., minimizing $\hat{\Psi}_4(t)$, our energy management scheme leads to the control decisions that maximizes $c^i_{\text{max}}$. Due to constraint (7), we have $d_i(t) = 0$. Therefore, according to (4), we get $x_i(t + 1) = x_i(t) + c_i(t)$ and hence

$$0 \leq x_i(t + 1) \leq d^i_{\text{max}} + c^i_{\text{max}} \leq x^i_{\text{max}}$$

due to constraint (13).

- If $d^i_{\text{max}} \leq x_i(t) \leq V^{\gamma^\text{max}} + d^i_{\text{max}}$. Since

$$V \leq V^{\gamma^\text{max}} \leq \frac{x^i_{\text{max}} - c^i_{\text{max}} - d^i_{\text{max}}}{\gamma^\text{max}},$$

we have $x_i(t) \leq x^i_{\text{max}} - c^i_{\text{max}}$. Thus, according to (4), we can obtain

$$x_i(t + 1) \leq x^i_{\text{max}} - c^i_{\text{max}} + c_i(t) - d_i(t) \leq x^i_{\text{max}}$$

and

$$x_i(t + 1) \geq d^i_{\text{max}} + c_i(t) - d_i(t) \geq 0.$$ 

Thus, our energy management scheme minimizing $\hat{\Psi}_4(t)$ results in control decisions that satisfy $d_i(t) = d^i_{\text{max}}$. Due to constraint (9), we have $c_i(t) = 0$. Thus, according to (4), we get $x_i(t + 1) = x_i(t) - d^i_{\text{max}}$ and hence $0 \leq x_i(t + 1) \leq x^i_{\text{max}} - d^i_{\text{max}} \leq x^i_{\text{max}}$.

Therefore, we can see that (10) holds for all $t \geq 0$, and hence (32) holds as well.

6.2 Lower and Upper bounds on $\psi^*_P$

In what follows, we obtain both lower and upper bounds on the optimal results of $P1$, i.e., $\psi^*_P$.

Theorem 4: The solution obtained from our proposed algorithm serves as a suboptimal yet feasible solution to $P1$, and the corresponding time-averaged expected amount of energy cost works as an upper bound on the optimal result of $P1$, i.e., $\psi^*_P \leq \psi_P$.

Proof: The proposed decomposition based algorithm finds a solution that satisfies all the constraints in $P3$, i.e., (9)-(14), (16)-(19), (22)-(25), and (44). Thus, the solution is also a feasible solution to $P1$, and the corresponding time-averaged expected energy cost, i.e., $\psi_P$, is no less than the optimal result of $P1$, i.e., $\psi_P \geq \psi^*_P$.

Next, we find a lower bound on $\psi^*_P$. We first present a lemma as follows.

Lemma 2: The time-averaged expected amount of energy cost achieved by optimally solving $P3$, denoted by $\psi^*_P$, is within a constant gap $\frac{B}{\gamma^\text{min}}$ from the minimum time-averaged expected energy cost achieved by $P2$, i.e., $\psi^*_P$. Particularly, we have $\psi^*_P - \frac{B}{\gamma^\text{min}} \leq \psi^*_P$ where $B$ and $V$ are defined in Section 5.2.

Proof: Denote by $\alpha^m_{ij}(t)$, $\beta^m_{ij}(t)$, $\tilde{\alpha}^m_{ij}(t)$, $\tilde{\beta}^m_{ij}(t)$, $\tilde{c}^m_{ij}(t)$, $\tilde{d}^m_{ij}(t)$, and $f^m(P(t))$ the results obtained by our proposed scheme in time slot $t$, i.e., based on the optimal solution to $P3$. We also denote by $\alpha_{ij}(t)$, $\beta_{ij}(t)$, $\tilde{\alpha}_{ij}(t)$, $\tilde{\beta}_{ij}(t)$, $\tilde{c}_{ij}(t)$, $\tilde{d}_{ij}(t)$, and $f(P(t))$ the results that we get for time slot $t$ based on the optimal solution to $P1$. Thus, from Lemma 1,
we can have
\[
\Delta(\Theta(t)) + V E[f(P(t)) - \lambda \sum_{s \in S} \sum_{i \in B} k_s(t) \cdot 1_{i=s}(t) | \Theta(t)] \\
\leq B + \Psi_1(t) + \Psi_2(t) + \Psi_3(t) + \Psi_4(t) \\
\leq B + V E[f^*(P(t)) - \lambda \sum_{s \in S} \sum_{i \in B} k_s(t) \cdot 1_{i=s}(t)] \\
+ \hat{\Psi}_1(t) + \hat{\Psi}_2(t) + \sum_{s \in S} \sum_{i \in N} (Q_s^i(t)(k_s^i(t) \cdot 1_{i=s}(t))) \\
+ \sum_{i \in N} (z_i(t)(c_s^i(t) - d_s^i(t))) \\
= B + V E[f^*(P(t)) - \lambda \sum_{s \in S} \sum_{i \in B} k_s(t) \cdot 1_{i=s}(t)] \\
+ \sum_{i \in N} \sum_{j \in N} Q_s^i(t) \lim_{T \to \infty} \frac{1}{T} \sum_{t=0}^{T-1} (l_{ij}^s(t) + k_s^i(t) \cdot 1_{i=s}(t)) \\
- t_{ij}^s(t) + \sum_{i \in N} \sum_{j \in N, j \neq i} H_{ij}^s(t) \lim_{T \to \infty} \frac{1}{T} \sum_{t=0}^{T-1} \left( \sum_{s \in S} \beta_i h_{ij}^s(t) \right) \\
- \frac{\beta}{\delta} \sum_{m \in M_i \cap M_j} c_m^i(t) u_{ij}^m(t) \Delta t \\
+ \sum_{i \in N} z_i(t) \lim_{T \to \infty} \frac{1}{T} \sum_{t=0}^{T-1} (c_s^i(t) - d_s^i(t))
\]

Note that the third step is due to the fact that the optimal solutions to P1 are obtained independent of the current queues \( \Theta(t) \). The fourth step is due to the strong law of large numbers: If \( \{a(t)\}_{t=0}^\infty \) are i.i.d. random variables, we have \( \Pr(\frac{1}{T}\sum_{t=0}^{T-1} a(t) = E[a(t)]) = 1 \) almost surely. Consequently, taking expectation of the above inequality yields:

\[
E[\hat{L}(\Theta(T+1))] - E[\hat{L}(\Theta(T))] \\
+ V E[f(P(t)) - \lambda \sum_{s \in S} \sum_{i \in B} k_s(t) \cdot 1_{i=s}(t)] \\
\leq B + V E[f^*(P(t)) - \lambda \sum_{s \in S} \sum_{i \in B} k_s(t) \cdot 1_{i=s}(t)] \\
+ \sum_{i \in N} \sum_{j \in N, j \neq i} Q_s^i(t) \lim_{T \to \infty} \frac{1}{T} \sum_{t=0}^{T-1} \left( E[l_{ij}^s(t) + k_s^i(t) \cdot 1_{i=s}(t)) \\
- t_{ij}^s(t) + \sum_{i \in N} \sum_{j \in N, j \neq i} H_{ij}^s(t) \lim_{T \to \infty} \frac{1}{T} \sum_{t=0}^{T-1} \left( \sum_{s \in S} \beta_i h_{ij}^s(t) \right) \\
- \frac{\beta}{\delta} \sum_{m \in M_i \cap M_j} c_m^i(t) u_{ij}^m(t) \Delta t \\
+ \sum_{i \in N} z_i(t) \lim_{T \to \infty} \frac{1}{T} \sum_{t=0}^{T-1} (c_s^i(t) - d_s^i(t))
\]

Since we have prove the strong stability of \( Q(t), H(t) \) and \( z(t) \), we know that \( Q(t), H(t) \) and \( z(t) \) are also rate stable, according to Theorem 2. So we can have:

\[
\sum_{s \in S} \frac{\beta_i}{\lambda} \sum_{m \in M_i \cap M_j} \alpha_{ij}^m(t) \Delta t \leq 0 \\
\sum_{s \in S} \frac{\beta_i}{\delta} \sum_{m \in M_i \cap M_j} \alpha_{ij}^m(t) \Delta t \leq 0 \\
\sum_{s \in S} \frac{\beta_i}{\delta} \sum_{m \in M_i \cap M_j} \alpha_{ij}^m(t) \Delta t \leq 0
\]

Therefore, we can obtain

\[
E[\hat{L}(\Theta(T+1))] - E[\hat{L}(\Theta(T))] \\
+ V E[f(P(t)) - \lambda \sum_{s \in S} \sum_{i \in B} k_s(t) \cdot 1_{i=s}(t)] \\
\leq B + V E[f^*(P(t)) - \lambda \sum_{s \in S} \sum_{i \in B} k_s(t) \cdot 1_{i=s}(t)]
\]

Summing the above over \( t \in \{0, 1, 2, \ldots, T-1\} \) for any positive integer \( T \) yields

\[
E[\hat{L}(\Theta(T))] - E[\hat{L}(\Theta(0))] \\
+ V \sum_{t=0}^{T-1} E[f(P(t)) - \lambda \sum_{s \in S} \sum_{i \in B} k_s(t) \cdot 1_{i=s}(t)] \\
\leq TB + V \sum_{t=0}^{T-1} E[f^*(P(t)) - \lambda \sum_{s \in S} \sum_{i \in B} k_s(t) \cdot 1_{i=s}(t)]
\]

Since all queues are finite in all time slots, dividing both sides of (48) by \( VT \) and taking limits as \( T \to \infty \) lead to

\[
\lim_{T \to \infty} \frac{1}{T} \sum_{t=0}^{T-1} E[f(P(t)) - \lambda \sum_{s \in S} \sum_{i \in B} k_s(t) \cdot 1_{i=s}(t)] \\
\leq \lim_{T \to \infty} \frac{1}{T} \sum_{t=0}^{T-1} E[f^*(P(t)) - \lambda \sum_{s \in S} \sum_{i \in B} k_s(t) \cdot 1_{i=s}(t)] + \frac{B}{V},
\]

which means \( \psi_{p2} \cdot B \leq \psi_{p2} \cdot V \)

Recall that P1, P2 and P3 are both Mixed-Integer Programming problems. We relax P2 to a Linear Programming (LP) problem without the strong stability constraint (26) denoted by P3, and formulate a corresponding online energy cost minimization problem denoted by P3̄. We can see that P3̄ is a relaxed LP problem based on P3 without the strong stability constraint (44), which can be easily solved. Denoted by \( \psi_{p3} \) and \( \psi_{p3} \), the time-averaged expected amount of energy cost obtained by optimally solving P1 and P3̄, respectively, based on Lemma 2, we can know that \( \psi_{p3} \leq \psi_{p2} \leq \psi_{p3} \). Since obviously we also have \( \psi_{p3} \leq \psi_{p2} \leq \psi_{p3} \), we can arrive at the following result.

**Theorem 5**: The optimal result of P1 is lower bounded by \( \psi_{p3} \cdot B \leq \psi_{p3} \cdot V \), where \( \psi_{p3} \) can be obtained by optimally solving P3̄.

### 7 Simulation Results

In order to complement the analysis in the previous sections, we carry out extensive simulations to evaluate the performance of our proposed scheme. Our goals are to obtain the lower and upper bounds on the optimal result of P1, to examine the trade-off between energy cost and queue size, and to demonstrate the energy efficiency of our scheme compared with that of other similar energy management strategies. Simulations are
The energy generation cost function, i.e., $f$, the power grid in a time slot, i.e., $\max_i p_i$, the maximum amount of energy that each node can draw from the grid in a time slot, i.e., $\max_i p_i$.

The transmission power, which is $\forall i \in U$, is defined as $p_i = 0$, $\forall i \in U$, respectively, and 20 users are randomly distributed. Besides, we assume there is one cellular band with bandwidth 1 MHz and four other spectrum bands whose bandwidth is independently and uniformly distributed within [1, 2] MHz in each time slot. Only a random subset of the spectrum bands are available at each mobile user while base stations can access all the bands. There are four service sessions whose destination nodes are randomly chosen. Each session has a traffic demand of 1 Kbps. Some other important simulation parameters are listed as follows. The path loss exponent is 4 and $C = 62.5$. The SINR threshold is $\Gamma = 1$. The noise power spectral density is $\eta = 10^{-20}$ W/Hz at all nodes. All nodes ($\forall i \in U$) have the same maximum transmission power, which is $P_{\text{max}} = 1$ W while base stations have much larger transmission power, i.e., 20 W. In addition, nodes’ renewable energy generation capabilities are determined according to the global horizontal irradiance data in Las Vegas area from the Measurement and Instrumentation Data Center [47]. We assume that the energy conversion efficiency is 15% and the maximum outputs of mobile users’ and base stations’ renewable energy resources are 1 W and 15 W, respectively, in each time slot. The maximum charging and discharging limits on each user’s energy storage device in a time slot, i.e., $c_i^{\text{max}}$ and $d_i^{\text{max}}$, are both set to 0.06 kWh for mobile users and 0.1 kWh for base stations. The maximum amount of energy that each node can draw from the power grid in a time slot, i.e., $P_{\text{max}}^i$, is set to 0.2 kWh. The energy generation cost function, i.e., $f(P(t))$, is defined as $f(P(t)) = aP^2(t) + bP(t) + c$, where $a = 0.8$, $b = 0.2$ and $c = 0$. All our results presented below are collected after the experiments run for a period of $T = 100$ time slots, the duration of each of which is set to 1 minute.

In Fig. 2(a), we show both the upper and lower bounds on the optimal result of P1. Recall that the upper bound is achieved by our proposed algorithm, i.e., $\psi_{P3}$, and the lower bound is obtained by optimally solving the relaxed problem $\mathcal{P3}$, i.e., $\psi - B / V$. We can find that the lower and upper bounds get closer to each other as $V$ increases.

Then, we examine the tradeoff between energy cost and the queue backlog sizes incurred by our scheme. We find that in Fig. 2(b) and Fig. 2(c), the data queue backlog sizes of base stations and mobile users increase as time goes by and are bounded. We can also get similar results in Fig. 2(d) and Fig. 2(e) for energy queues. Since the expected total sizes of all data queues and energy buffers of both mobile users and base stations are all finite, each single data queue and energy buffer in the network are finite in each time slot, therefore guaranteeing the strong stability of the network. Besides, a larger $V$ results in a larger queue backlog size. This is because a larger $V$ means more emphasis on the energy cost minimization than on the queue size and that the system needs to have a larger queue buffer so as to save more energy cost. The results in Fig. 2(a)-2(e) together show the tradeoff between energy cost minimization and queue length in our proposed algorithm.

Next, we compare the time-averaged expected energy cost of our proposed architecture with those of other cellular network architectures, i.e., multi-hop network without renewable energy, one-hop network with renewable energy, and one-hop network without renewable energy. As shown in Fig. 3(a),...
Fig. 3. Performance comparison of different architectures.

our system has the lowest time-averaged expected energy cost among these four network systems when $V$ goes from $1 \times 10^5$ to $5 \times 10^5$. Specifically, compared with the multi-hop network without renewable energy, our system can take advantage of the renewable energy and the energy stored locally and hence save energy cost. In addition, by comparing one-hop and multi-hop networks, we can find that the latter have lower energy cost. This is because multi-hop technology enables nodes in the network to use lower transmission power to help each other with the transmissions and hence reduce energy consumption.

Similarly, in Fig. 3(b) and Fig. 3(c), we examine how the time-averaged expected energy cost changes when the number of base stations varies from 1 to 5 and the number of mobile users varies from 20 to 25 in these four systems mentioned above. Specifically, in Fig. 3(b), we set $V$ to $5 \times 10^5$ and the number of mobile users to 20. We find that when the number of base stations increases, the time-averaged expected energy costs decrease in all the four systems, an interesting result. This is because first, more base stations means more renewable energy resources, and second, when there are more base stations, we can choose the optimal one as the source for each destination node and thus save more energy. We can clearly see that our architecture achieves the lowest energy cost. Besides, when the number of mobile users increases from 20 to 25, where $V$ is equal to $5 \times 10^5$ and there are two base stations, we can see in Fig. 3(c) that while the time-averaged expected energy cost shows little change in one-hop networks, it decreases noticeably in multi-hop networks. One main reason is that more mobile users can result in more efficient multi-hop relaying and hence lower energy consumption. Our proposed architecture still achieves the lowest energy cost.

In this paper, we propose an energy cost minimization framework for downlink data communication in multi-hop cellular networks. In particular, with the objective of minimizing the long-term time-averaged expected energy cost of cellular service provider while guaranteeing the strong stability of the network, we construct a time-coupling stochastic Mixed-Integer Non-Linear Programming (MINLP) problem, which is prohibitively expensive to solve. By employing Lyapunov optimization theory, we reformulate the problem and develop a decomposition based scheme to solve the problem in each time slot without priori knowledge of the network statistics. The proposed scheme can ensure the network strong stability. Both the lower and upper bounds on the optimal result of the original optimization problem are obtained. Extensive simulation results validate the energy cost savings of the proposed scheme.
